ABSTRACT: Nanoscale generation of individual photons in confined geometries is an exciting research field aiming at exploiting localized electromagnetic fields for light manipulation. One of the outstanding challenges of photonic systems combining emitters with nanostructured media is the selective channelling of photons emitted by embedded sources into specific optical modes and their transport at distant locations in integrated systems. Here, we show that soft-matter nanofibers, electrospun with embedded emitters, combine subwavelength field localization and large broadband near-field coupling with low propagation losses. By momentum spectroscopy, we quantify the modal coupling efficiency identifying the regime of single-mode coupling. These nanofibers do not rely on resonant interactions, making them ideal for room-temperature operation, and offer a scalable platform for future quantum information technology.

KEYWORDS: nanofiber, nanophotonics, colloidal quantum dots, single photon, momentum spectroscopy, all-dielectric waveguide

Light–matter interaction design in nanostructured optical environments has revolutionized the nanoscale control of light emission, absorption, and transport. Exerting such control on single-photon sources can be a fundamental step toward integrated photonic systems, with applications including single-photon transistors, on-chip generation and routing of single photons, quantum interference, or long-range coupling of single emitters.

In this framework, plasmonic systems, which exploit near-field interactions in narrow gaps or nanosized resonators, have attracted much attention for broad-band and room temperature operation: plasmonic nanoantennas can increase the directionality and decay-rate of single-photon sources, whereas the emitted photons can be transported to distant locations by plasmon modes in metal nanowires, wedges, or V-groove metal surfaces.

Inspired by plasmonic architectures, subwavelength dielectric nanostructures are emerging as candidate materials for light management at room-temperature. Unlike photonic crystals, which exploit long-range interference (over many wavelengths) to design narrow resonance modes, subwavelength dielectrics offer practical local field enhancements and the ability of near-field light manipulation with the advantage of being free of the metal optical losses.

Indeed, these waveguides can channel and transport light from a single emitter across long distances with relatively low losses, realizing a simple interface between light emitters and propagating modes, increasing off-chip extraction efficiency with diamond nanowires and semiconductor nanopillars. Moreover, the interaction of an emitter with a subwavelength waveguide allows for the exploitation of unique phenomena, such as spin–orbit coupling and unidirectional emission, which occurs only when light is spatially confined.

Polymer subwavelength waveguides fabricated by self-assembly, drawn from polymer solutions and melts, are a promising system compatible with integration of quantum dots or molecules as emitters, and with potential for scalability and interconnection to form networks in 2-dimensions and 3-dimensions. This improves on conventional pulled silica fibers with emitters evanescently coupled on the nanofiber surface and on pulled capillary hosting single molecules. Moreover, these waveguides are cavity-free and with a broadband response, which makes them ideal for room-temperature (where sources are broadband) and ultrafast operation and for further interfacing with biological matter.
Although polymer nanofibers do not require nanolithography or top-down nanofabrication to be realized, the emitter-waveguide coupling has to be assessed a posteriori. In this respect, characterizing the different modal contributions is important for further optical engineering of the propagation and coupling properties, and for quantum applications. The coupling efficiency can be probed from the collected scattered and transmitted light when the waveguide terminals are accessible,\textsuperscript{5,29} by measuring the excitation extinction,\textsuperscript{30} or when coupling to strong resonances from indirect estimations, such as those drawn from the lifetime variations of on- and off-coupling.\textsuperscript{19,31} To date, quantifying the coupling efficiency of a single emitter to a specific nanofiber mode, in a way valid also for subwavelength and weakly resonant modes, is an outstanding challenge.

Here, we report broadband single-photon generation and transport from isolated quantum dots embedded in the core of a free-standing and subwavelength polymer nanofiber. By means of momentum spectroscopy, we record the full $k$-vector distribution of the light emitted by individual quantum dots, revealing the selective coupling of the different dipole orientations to the individual nanofiber modes. We find a coupling to the fundamental mode with values up to $\beta_0 = (31 \pm 2)\%$ which compare well with the theoretical maximum coupling of $\beta_0 = 53\%$. 

**RESULTS AND DISCUSSION**

The hybrid nanofiber-emitter system is designed for (i) maximal coupling, by embedding the emitter at the nanofiber core, and (ii) efficient long-range transport, which is achieved by a free-standing geometry. The nanofibers are fabricated by electrospinning a polymethylmetacrylate (PMMA) solution (see Methods) doped with CdSeTe colloidal quantum dots (Invitrogen QD800, emission peaked at 790 nm). Unlike electron-beam or focused ion-beam lithography, the electrospinning process largely preserves the integrity of embedded organic and inorganic light emitters.\textsuperscript{26} Doped fibers with a diameter ($D$) between 300 and 1000 nm, depending on the processing parameters, are deposited either (i) on a glass substrate or (ii) on a transmission electron microscopy (TEM) grid producing free-standing nanostructures, with a circular cross section and length of tens to hundreds of micrometers with isolated quantum dots. A scanning electron microscopy (SEM) image of a typical free-standing nanofiber is shown in Figure 1a. When illuminated with a red laser (632 nm), the emitters can be located via wide-field fluorescence imaging, as in Figure 1b. The emission dynamics is studied by confocal microscopy (numerical aperture, NA = 0.95) and time correlated single-photon counting (TCSPC). Hanbury Brown and Twiss interferometry of the quantum dots in free-standing nanofibers using two avalanche photodiode (APD) in start–stop configuration is shown in Figure 1c. The intensity correlation function $g_2(t)$ measured under continuous wave (CW) excitation (power 12 $\mu$W, wavelength 633 nm) is fitted to $g_2(t) = A(1 - (1/N)\exp(|l|/r'))$, which gives a second-order intensity correlation function at zero-time, $g_2(0) = 0.10 \pm 0.03$, and a corresponding decay-time $r' = (84 \pm 3) \text{ ns}$, which confirms single-photon emission. The excited state lifetime for the quantum dot is measured under picosecond pulsed excitation (average power 1.5 $\mu$W, repetition rate 2.5 MHz, wavelength 634 nm). In the specific case shown in Figure 1d, a single exponential fit gives a decay time $\tau = (137 \pm 0.1) \text{ ns}$. The difference between $\tau$ and $r'$ can be explained via an incoherent repumping term $R$, with $r' = ((1/r) + R)^{-1}$, as in ref 32. Fluorescence lifetime statistics of individual quantum dots inside free-standing nanofibers show a decay rate reduction of $\sim 25\%$ as compared to a reference homogeneous polymer film, in agreement with the theoretical prediction (Supporting Information Figure S1). The decay rate of an emitter inside a subwavelength nanofiber is expected to be weakly reduced, due to the low refractive index of PMMA ($n_{PMMA} = 1.49$, see Supporting Information Figure S1). Light collected from the nanofiber-coupled quantum dots has a typical blinking behavior with an off state of 300 counts/s (Figure 1e).

For a quantum dot in the nanofiber, the quantum dot saturation intensity is 7 $\text{kW cm}^{-2}$, achieved at an average pump intensity of 0.5 $\mu$W in a diffraction-limited illumination area (air objective, NA = 0.95), for which we have measured 38 kphotons/s emitted, with an expected maximum count-rate ($S_{max}$) of 42 kphotons/s (see Supporting Information Figure S2). Above saturation the quantum dot approaches one photon emitted per excitation pulse, that is, 2.5 Mphotons/s, given our laser repetition rate of 2.5 MHz, limited by the less than unitary...
quantum efficiency (~0.7, as provided by the manufacturer, Invitrogen) and by the off-states of the quantum dot (~30% on-state due to blinking) to a value of ~0.5 Mphotons/s.

Momentum spectroscopy of the emitted light directly accesses the coupling of the emitter to the nanofiber modes and allows us to calculate the modal coupling in an original way, without measuring the light transported by the nanofiber. Here, we apply Fourier patterns analysis which is emerging as a reliable quantitative tool to probe otherwise inaccessible information about the emitter and its emission directionality. We measure the light emitted in momentum space by recording the angular patterns of the radiation emerging from a quantum dot inside a nanofiber lying on glass. Index matching enables access to large angles, up to the 1.45 numerical aperture (NA) of our objective, which encompasses the wave-vectors of the guided modes beyond the air light-line. We collect Fourier patterns as shown in Figure 2a and b for two nanofibers: a thin one, in the single mode regime ($D/\lambda = 0.5$, Figure 2a) and a thick one, in the multimode regime ($D/\lambda = 0.9$, Figure 2b). Each pair of momenta lobes (positive and negative $k_x$ where $x$ is the direction of the longitudinal axis of the nanofiber) beyond the air light-line ($|k_x| > 1$), elongated in a direction orthogonal to the nanofiber, is the $k$-vector distribution of the distinct nanofiber modes. This is a clear experimental signature of the individual coupling of the quantum dot to each of the nanofiber modes, which is in very good agreement with the calculated Fourier patterns shown in Figure 2c and d.

Figure 2e plots the mode dispersion structure reconstructed from the calculated angular pattern of a dipolar source in the center of a nanofiber (see Methods). The intensity map indicates the coupling strength of a longitudinal (blue) and transverse (red) dipole to the nanofiber, normalized to unity, which is the maximal value in the plot. The guided modes are visible as two lines that stem from the air light-line $c_0 k_x$ growing to larger $k$-vectors up to the polymer light-line $\omega = c_0 k_x / n$, where $\omega$ is the light frequency, $c_0$ the speed of light in vacuum, and $n$ the refractive index. Because of the different spatial symmetry of the modes, the transverse (red) dipole couples almost exclusively to the fundamental mode $LP_{01}$, and the longitudinal (blue) to the second higher mode $LP_{11}$. Instead, the light emitted inside the light cone in air ($\omega > c_0 k_x$) corresponds to uncoupled radiation, emitted into free-space modes. We confirm this selective coupling and the nature of the modes by superimposing the analytical solution (dashed white lines) of the dispersion relations of the modes for a free-standing nanofiber. The analytical solution matches the maxima of the coupling of the two dipole-orientations which confirms that the strength of the momenta peak is a direct measure of the coupling of the emitter to a specific wave-vector, that is, to a specific nanofiber mode.

Coupling of an emitter to the propagating waveguide modes is required for transport and manipulation of the emitted single photons. Plasmonic nanostructures can offer very high coupling efficiencies, as high as 21% for silver nanowires or 42% for V-groove channels, although propagation of coupled photons is limited by the strong Ohmic losses in the metal. Instead, dielectrics can offer much longer propagation length at the price of a weaker coupling, which has been measured at room-temperature to reach ~30% for quantum dots outside a silica nanofiber, approaching experimentally the theoretical limit imposed by evanescent coupling. Higher values, close to 100%, can be reached at cryogenic conditions for the coupling of epitaxial quantum dots to photonic crystal waveguides.

although this is limited to narrow-band resonance, or ~18% for single molecules inside a broadband pulled glass capillary.

Here, we developed a different technique based on the momentum spectroscopy of the emitted light; from the ratio of the coupled and uncoupled light, the total coupling constant $\beta$ as well as the coupling to the fundamental mode $LP_{01}$ can be estimated. The coupling efficiency $\beta$ is obtained as the ratio between the light emitted into the guided modes region ($|k_x| > 1$) and the total emitted light $\beta = (I(k_x > 1)/I$, whereas $\beta_{LP_{01}}$ is the ratio between the intensity of the $k$-vector corresponding to the mode $LP_{01}$ and the total emitted light (see Methods). The obtained coupling values are shown in Figure 3, where the lines represent the theoretical predictions and the points indicate the experimental data. Although the total coupling $\beta$ remains roughly constant for all diameters (see Supporting Information).
The momentum spectroscopy method here developed is also useful for single mode nano-illumination. The granularity of the quantum dot doping prevents a uniform coupling. Additional modes become available. The measured coupling values (green bars in Figure 3) are in the range $\beta_{01} = (21 \pm 4)\% - (31 \pm 2)\%$ for single mode nano-illuminations, and $\beta_{01} = (5 \pm 1)\% - (15 \pm 1)\%$ for multimode nanoilluminations, where also the coupling to the second higher mode $\beta_{11}$ increases (orange bars in Figure 3). The errors come from the uncertainty in the position of the peaks in the $k$-space. The accuracy of this estimation can be confirmed by FDTD calculations that show an agreement within 10% between the values of $\beta$ obtained from the two methods of momentum spectroscopy and direct modal coupling (see Supporting Information and Figure S4). As expected, the experimental values are lower than the theoretical prediction for a transverse or longitudinal dipole, as the quantum dot’s dipole moment is randomly oriented in the nano-fiber surface roughness (a few nanometers) as measured by atomic force microscopy.

As both long propagation and large coupling are important criteria to assess the quality of an hybrid nanoscale architecture, the most recent figure of merit (FOM) introduced by Bermúdez-Ureña et al. combines them in the product $(\beta P) x / \lambda$, of mode coupling $(\beta)$, Purcell factor $(P)$, and propagation length $(x)$ normalized by free-space operating wavelength $(\lambda)$. We suggest here that $\beta$ is replaced by the modal coupling, that is, $\beta_{01}$ for the fundamental mode, which has more practical importance for single-mode operation. The state-of-the-art in plasmonic systems is reported to be FOM = 6.6 ± 23%, whereas for our dielectric nanoilluminations, we can calculate a FOM of $44 \pm 16\%$ coming from a coupling of $\beta_{01} = (31 \pm 2)\%$ and a Purcell factor with respect to vacuum of $1.2 \pm 15\%$ and the propagation length $x = (95 \pm 5) \mu m$. Although plasmonic systems can strongly engineer the Purcell factor, dielectric nanostructures, with negligible Ohmic losses, offer longer propagation lengths, resulting in a large FOM. This FOM is useful to compare nanoscale geometries, whereas it loses importance for macroscopic systems such as conventional single mode fibers for which the very long propagation length dominates the FOM.

CONCLUSIONS

In conclusion, we report on a nano-fiber single-photon light source architecture, integrating a quantum emitter into a low
loss single mode optical waveguide and operating at room temperature. Using an approach based on momentum spectroscopy, we have quantified the coupling efficiency of individual quantum dots to each nanofiber mode, obtaining broadband coupling of up to 31% of the emitted light (see also Supporting Information Figure S5) and a FOM of 44 ± 16%.

Through their robustness and flexibility, these nanofibers have potential as a future platform for nanoscale quantum optics as they can be connected to form a network of coupled emitters for quantum technological applications. Moreover, these systems are compatible with plasmonic systems, and therefore suitable for further photonic engineering.

METHODS

Nanofibers Fabrication. One nM solution containing CdSeTe quantum dots (Invitrogen QD800, emitting at 790 nm) was mixed with a chloroform solution of PMMA (MW 120 000, Sigma-Aldrich). In order to obtain submicron fibers, 30 mg of tetrabutylammonium iodide organic salt was added to the solution. By measuring the emission spectrum of the quantum dots, we checked that the solvent, polymer matrix, and organic salt do not affect the photoluminescence properties of the embedded emitters. The background fluorescence from PMMA is estimated to be <1% of the emission from the QD, as determined both by measuring the background fluorescence collected from the excited spot and by exciting 10 μm away from the edge of an intentionally cut nanofiber and collecting at the edge (see Supporting Information Figure S5). For light transport measurements, the IR-140 organic chromophore was added to the PMMA solution, using a concentration of 0.1% weight:weight relative to the PMMA-polymer matrix. The solution was loaded in a 1 mL syringe tipped with a 27G gauge stainless steel needle and delivered at 0.5 mL h⁻¹ constant rate by means of a syringe pump (Harvard Apparatus, Holliston, MA). A bias voltage of 8 kV was applied between the needle and the metallic collector by a high voltage power supply (Glassman High Voltage).

Glass coverslip substrates (18 × 18 mm²) were placed on a 10 × 10 cm² Cu plate used as grounded collector, positioned 10 cm away from the needle. Free-standing nanofibers were obtained by deposition on a TEM grid (TAAB Laboratories Equipment Ltd.) used as collector. Electrospinning was performed with a relative humidity and temperature of about 40% and 25 °C, respectively. Reference thin films on glass coverslip substrates were obtained by spin-coating the solution used for electrospinning at 6000 rpm for 40 s. The nanofiber morphology was investigated by SEM (FEI Nova NanoSEM 450 or Zeiss) and atomic force microscopy (Veeco Instruments). The fiber diameters were in the range of 300–1000 nm, with a surface roughness (root-mean-square, RMS) of the order of few nm. The fibers have almost a round-shaped cross section (Figure S6a,b), with a ratio between the height and the width in the range 0.9–1. A maximum variation of 70 nm of the fiber diameter over a length of 1 mm was measured (Figure S6c–h).

Confocal Optical Microscopy. The excited state lifetime of isolated quantum dots was measured by confocal microscopy and TCSPC (TimeHarp 260, PicoQuant) with an overall temporal resolution of ~100–200 ps. The quantum dots were excited with a 100 ps, 634 nm, 2.5 MHz repetition rate laser (average power 1.5 μW) through an air objective (NA = 0.95) or an oil immersion objective (NA = 1.45). The light emitted was collected by the same objective through an air objective (NA = 0.95) or an oil immersion objective (NA = 1.45). The collection efficiency was obtained by the same objective and directed to an avalanche photodiode (APD). The lifetime traces were fitted with both a single exponential and a log-normal model, and the one providing the highest accuracy was retained. Antibunching was measured through the same setup, but using two APDs in start–stop configuration. The intensity correlation function g₂(t) measured from a quantum dot under CW excitation was fitted to g₂(t) = A(1 − (1/N) exp(−t/τ)). The collection efficiency of our microscope is estimated to be ~5% for polymer films and 1.45 NA oil immersion objective and ~2–3% for free-standing fibers and 0.95 NA air objective. These values are obtained as the ratios between the measured saturation intensity of several individual QDs and the expected emission intensity at saturation (laser repetition rate times the quantum efficiency).

Optical Fourier Imaging. We recorded the angular emission patterns I(kₓ, kᵧ) of isolated quantum dots by imaging the back-focal plane into a CCD camera (Princeton Instruments, PiXis 400). The excitation and collection was achieved through an oil immersion objective (100x, NA = 1.45). We calculated the intensity distribution I(kₓ) = Σ I(kₓ, kᵧ), where kᵧ is the component of k along the nanofiber axis. We estimated the nanofiber diameter D by comparing the position of the peaks in the experimental Fourier patterns with the theoretical modal dispersion. As the nanofiber modes are only marginally affected by the glass interface, the light emitted in the k-regions beyond the light-cone in air corresponds to guided modes (kₓ > 1), and the light inside the light cone in air to the uncoupled modes. For multimodal fibers, owing to the modes’ orthogonality in k-space, different modes have different wave vectors for the same energy; this allows assessing the individual coupling to these modes by measuring the relative strength of the Fourier peaks. In this way, the coupling to the fundamental mode β₀ can be separated from the total coupling β to all the waveguide modes.

The coupling efficiency β is obtained as the ratio between the light emitted into the guided modes region (kₓ > 1) and the total emitted light

\[ \beta = \frac{I(k_x > 1)}{I_{total}} \]

while β₀ is the ratio between the intensity of the k-vector corresponding to the mode LP₀₁ and the total emitted light. This can be generalized for all other higher-energy modes.

An uncertainty is attributed to both D and β due to the uncertainty in the k-space calibration that we quantify as 0.05. The accuracy of this estimation can be confirmed by finite difference time domain (FDTD) calculations that show an agreement within 10% between the values of β obtained from the two methods of momentum spectroscopy and direct modal coupling (See Supporting Information Figure S4).

Numerical Calculations. FDTD simulations were performed using a commercial package (Lumerical). The local density of optical states (LDOS) maps were obtained by considering the intensity emitted by a dipolar source in different position inside the nanofiber. The total coupling efficiency was obtained by calculating the intensity transmitted through a monitor crossing the free-standing nanofiber 4 μm away from the source; the modal coupling efficiency was obtained by mode projection of the same intensity onto the independently calculated nanofibers modes. The angular patterns were obtained by means of far field projections of the electromagnetic fields in a plane 300 nm outside the nanofiber inside the substrate of a nanofiber laying on glass. Calculations with and without the glass substrate show that the low-refractive index interface below the nanofiber only weakly affects the modal dispersion, inducing only a spectral broadening due to the increased losses into the glass.
